Received 3 March 2005; accepted 13 April 2005

Chronic renal failure (CRF) represents a world health problem. Ozone increases the endogenous antioxidant defense system, preserving the cell redox state. The aim of this study is to evaluate the effect of ozone/oxygen mixture in the renal function, morphology, and biochemical parameters, in an experimental model of CRF (subtotal nephrectomy). Ozone/oxygen mixture was applied daily, by rectal insufflation (0.5 mg/kg) for 15 sessions after the nephrectomy. Renal function was evaluated, as well as different biochemical parameters, at the beginning and at the end of the study (10 weeks). Renal plasmatic flow (RPF), glomerular filtration rate (GFR), the urine excretion index, and the sodium and potassium excretions (as a measurement of tubular function) in the ozone group were similar to those in Sham group. Nevertheless, nephrectomized rats without ozone (positive control group) showed the lowest RPF, GFR, and urine excretion figures, as well as tubular function. Animals treated with ozone showed systolic arterial pressure (SAP) figures lower than those in the positive control group, but higher values compared to Sham group. Serum creatinine values and protein excretion in 24 hours in the ozone group were decreased compared with nephrectomized rats, but were still higher than normal values. Histological study demonstrated that animals treated with ozone showed less number of lesions in comparison with nephrectomized rats. Thiobarbituric acid reactive substances were significantly increased in nephrectomized and ozone-treated nephrectomized rats in comparison with Sham group. In the positive control group, superoxide dismutase (SOD) and catalase (CAT) showed the lowest figures in comparison with the other groups. However, ozone/oxygen mixture induced a significant stimulation in the enzymatic activity of CAT, SOD, and glutathione peroxidase, as well as reduced glutathione in relation with Sham and positive control groups. In this animal model of CRF, ozone rectal administrations produced a delay in the advance of the disease, protecting the kidneys against vascular, hemorheological, and oxidative mechanisms. This behavior suggests ozone therapy has a protective effect on renal tissue by downregulation of the oxidative stress shown in CRF.

INTRODUCTION

CRF represents a world health problem; once established, it goes irreversibly to a final stage, provoking the patient death. In contrast with the capacity of the kidneys to regain function following acute renal injury, renal injury of a more prolonged nature often leads to progressive and irreversible destruction of nephron mass [1]. Such reduction of renal mass, in turn, causes structural and functional hypertrophy of surviving nephrons. This compensatory hypertrophy is due to an adaptive hyperfiltration mediated by increase in glomerular capillary pressures and flows. Eventually, these adaptations prove maladaptive, predisposing to sclerosis of the residual glomerular population [1, 2, 3, 4]. The intrarenal vasculature is the most affected structure, preventing an appropriate blood flow, favoring the glomerular sclerosis [1, 2, 3, 4, 5]. For that reason, the improvement of the rheological properties of the blood could delay the progression of the CRF.

Glomerulonephritis was the most common initiating cause of CRF in the past, possibly because of its more aggressive treatment. Now, diabetes mellitus and hypertensive renal diseases are leading causes of CRF. The inexorable course to renal failure often is accompanied by anemia, malnutrition, impaired metabolism of carbohydrates, fats, and proteins, impaired platelet function, and defective utilization of energy [1].

Reactive oxygen species (ROS) play a key intermediary role in the pathophysiologic processes of a wide variety of clinical and experimental renal diseases. It ranges from acute to chronic injuries, making the kidney the site in which several unrelated diseases involve ROS [6]. ROS have been demonstrated to be capable of degrading glomerular basement membrane and inducing
glomerular injury, characterized by impaired glomerular filtration and sieving function [7, 8].

In order to eliminate toxic ROS, cells are equipped with various antioxidant defense systems. Therefore, the development of tissue injury depends on the balance between ROS generation and tissue antioxidant defense mechanism [9]. Among various antioxidant systems equipped within aerobic cells, three antioxidant enzymes, superoxide dismutase (SOD), glutathione peroxidase (GSH-Px), and catalase (CAT), are major mechanisms to reduce local levels of ROS. Thus, these enzymes distributed in cytosol and/or mitochondria can abase primary ROS, such as superoxide anion (by SOD) and hydrogen peroxide (by GSH-Px and CAT) before they can interact to form more reactive cytotoxic metabolites (hydroxyl radical or hypochlorous acid, among others). Studies in the past demonstrated that glomerular antioxidant enzymes levels are modulated. Thus, the glomerular antioxidant enzymes are suggested to play an important role in the functional derangement induced by the ROS [10].

CRF is associated with depressed SOD and elevated NADPH oxidase expression, which can contribute to oxidative stress by increasing superoxide anion [11]. Another metabolic disturbance associated with CRF is hyperlipidemia, closely related with decreased removal and increase of triacylglycerol production. Upregulation of fatty acid synthase (FAS) gene expression reveals another factor involved in disturbed lipid metabolism in CRF. It seems that elevated plasma insulin and cytokine concentration could play an important role in the mechanism responsible for the increased FAS gene expression in CRF [12].

Taking into account some of the ozone therapeutic properties, such as antiplatelet activity [13], enhancement of cell energy [14], and the increase of the antioxidant defense system [15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25], the aim of this paper is to evaluate the effect of ozone therapy in the renal function, morphology, and biochemical parameters that measure oxidative stress in an experimental model of CRF.

MATERIALS AND METHODS

Chemicals

All reagents used in determinations of GSH, SOD, CAT, GSH-Px, and thiobarbituric acid reactive substances (TBARS) were purchased from Sigma Chemicals (St Louis, Mo). Other reagents of analytical grade were obtained from normal commercial sources.

Animals

Thirty young female Wistar rats (180–200 g) were maintained in an air-filtered and temperature-conditioned room (20–22°C) with a relative humidity of 50%–52%. Rats were fed with standard laboratory chow and water ad libitum and were kept under an artificial light/dark cycle of 12 hours. The experiments were performed in accordance with the ethical guidelines for investigations in laboratory animals and were approved by the Ethical Committee for Animal Experimentation of the National Center for Scientific Research, Havana, Cuba.

Treatment schedule and surgical procedure

Ozone (O₃) was generated by OZOMED 01 equipment manufactured by the Ozone Research Center (Cuba). Ozone was obtained from medical-grade oxygen by means of a silent electric discharge, representing about 3% of the gas mixture (ozone/oxygen). The ozone concentration was measured by using a UV spectrophotometer at 254 nm. The ozone dose is the product of the ozone concentration, expressed as mg/L, by the gas mixture volume (L). By knowing the body weight of the rat, the ozone dose is calculated as 0.5 mg/kg.

Surgery was performed as previously described [26]. Ventral laparotomy was performed under aseptic conditions after anesthesia (sodium pentobarbital, 30 mg/kg intraperitoneal route). The right kidney was then removed, while two-thirds of the left kidney underwent acute infarction by ligation of two first-order branches of the main renal artery. Recovery from anesthesia and from the surgical procedure was complete within 24 hours.

Animals were allocated randomly to 3 experimental groups of 10 animals each: (1) Sham group (negative control group), where rats underwent a ventral laparotomy under anesthesia as described above; however, only handling of the renal pedicle without the removal of renal mass was performed; (2) positive control group, where rats were subjected to 5/6 renal ablation as described above; and (3) ozone group, where rats were handled as in group 2 but also received, after the damage, 15 sessions after anesthesia (sodium pentobarbital, 30 mg/kg intraperitoneal route). The right kidney was then removed, while two-thirds of the left kidney underwent acute infarction by ligation of two first-order branches of the main renal artery. Recovery from anesthesia and from the surgical procedure was complete within 24 hours.

Sample preparation

A day before the subtotal nephrectomy, all animals were housed in metabolic cages for 24 hours, without food and water ad libitum. In all animals, the weight and the systolic arterial pressure (SAP) in the tail, as well as protein excretion were measured. All these procedures and measurements were repeated, after the partial nephrectomy, once a week, for 10 weeks, the time during which, the CRF continued its evolution. The time of the study was not prolonged for more than 10 weeks, avoiding the unpredictable death due to the final stage of the CRF. In the last day of evolution, plasmatic clearance of p-aminohippurate (PAH) and inulin, in order to know the renal plasma flow (RPF) and the glomerular filtration rate (GFR), respectively, were determined using the method of unique injection (no urine) and the multicompartimental analysis of the plasmatic concentration curves in 9 blood samples [27]. Also, the urine excretion index (urine
volume/water ingested) and sodium and potassium excretions were determined in order to know tubular work. Creatinine in serum was determined in the final blood sample obtained by intracardiac puncture (2 mL of blood were extracted). Thereafter the animals were euthanized by ether anesthesia. The kidneys were dissected and immediately frozen at −20°C until analysis could be completed.

**Biochemical assays**

PAH and inulin were determined in deproteinized plasma samples by cadmium sulfate, using for PAH a photometric technique, modified by Smith and Tinkelstein [28]. Inulin was measured by the direct method of resorcinol without alkaline treatment [29]; corresponding calibration curves were used [30]. Proteins were calculated by the Biuret photometric technique using a Shimadzu spectrophotometer [31]. Potassium and sodium urine concentrations were measured for the calculation of the excretions of both substances in a Corning flame photometer (model 400), using the method described by Oser [32]. Creatinine in plasma was measured in deproteinated filtrates by the method of sodium urate. The kidney homogenates were obtained using a tissue homogenator Ultra-Turrax T25 polytron at 4°C. The homogenates were prepared by using a 100 mM KCl buffer (pH 7) containing EDTA 0.3 mM (1:10 w/v) for GSH, TBARS, GSH-Px, and SOD determinations (buffer 1). The homogenates were spun down with a centrifuge at 600g for 10 minutes at 4°C. The supernatants were taken for the biochemical determinations. GSH was determined by a slightly modified version of Beutler method [34], using a spectrophotometer. One mL of the kidney homogenate, as described before, was mixed with 1.5 mL of 5% metaphosphoric acid and centrifuged at 3000g for 10 minutes at room temperature. Fifty hundred microliters of this acidic supernatant was mixed with 2 mL of 0.2 M phosphate buffer and 0.25 mL of 0.04% 5,5′-dithio-bis-2-nitrobenzoic acid. Absorbance of the yellow solution was measured at 412 nm within 10 minutes. A molar extinction coefficient of 13.6 M cm⁻¹ that describes the formation of the thiolate anion by the reaction of sulphydryl groups with 5,5′-dithio-bis-2-nitrobenzoic acid (DTNB) at 412 nm was used to quantify GSH.

Enzymatic activity of SOD was determined by a modified version of Minami and Yoshikawa method [35]. One unit of SOD enzymatic activity is equal to the amount of enzyme that diminishes the initial absorbance of nitro blue tetrazolium by 50%.

CAT was determined according to Evans and Diplock method [36]. Kidney homogenates for CAT enzymatic assay were carried out using 50 mM phosphate buffer (pH 7) containing 1% Triton X-100 (1.9 w/v) (buffer 2). The enzyme activity is expressed as the first-order constant that describes the decomposition of H₂O₂ at room temperature.

Enzymatic activity of GSH-Px was measured using a modified version of Thonson et al method (see [37]). The enzyme activity is expressed as international units of enzymatic activity/mg of protein. International units are expressed as μmol of hydroperoxides transformed/min/mL of enzyme.

To estimate TBARS levels, a method described by Ohkawa et al. [38] was used. The absorbance of 3 mL of the colored layer was measured spectrophotometrically at 532 nm, using 1,1,3,3-tetraethoxypropane as a standard.

Protein concentrations were determined by the method of Lowry [39], using bovine serum albumin as a standard.

**Histological study**

Samples of rat kidneys were taken, fixed in 10% neutral buffered formalin, processed, and embedded in paraffin. A pathologist unaware of the treatment schedule examined the histological sections stained with hematoxylin and eosin.

**Statistical analysis**

First, the outliers preliminary tests for detection of error values were used. Afterward, the one-way analysis of variance (ANOVA) then homogeneity variance test (Bartlett-Box) were applied. In addition, Duncan’s multiple range test and the Student t test, for the comparison of two groups, were done. Results are presented as mean ± standard deviation (SD). Different letters indicate a statistical significance of at least P < .05.

**RESULTS**

At the end of the study (10 weeks after the partial nephrectomy), animals treated with ozone showed SAP figures lower than those in the positive control group, but higher values compared to those in Sham group (negative control group). Urine excretion index, in the ozone group, was similar to the negative control group; however, positive control group showed lower values compared to those in the other groups (Table 1). Compared to protein excretion and serum creatinine, figures, in the ozone group, were higher than those in the negative control group, but lower than those in the positive control group. Potassium and sodium excretion values in negative control and ozone groups were similar, but lower in the positive group compared to negative and ozone groups (Table 1). RPF and GFR in ozone and Sham groups showed similar figures, but they are higher compared to those in positive control group (Table 1).

Histological renal injuries (RI) were 0%, 13%, and 100% in the Sham, ozone, and positive control groups, respectively (Table 2). The histological findings for ozone and positive control groups were glomerular collapse (GC), tubule degeneration (TD), and cortical-medullary...
hemorrhages (CMH), with 100% for the positive control group compared with 20%, 10%, and 10%, respectively, for the ozone group. Convoluted tubules dilatation (CTD) and glomerular capsule dilatation (GCD) were similar for these groups, shown in 100% of animals. The histological study of renal cortex is observed in Figure 1. GCD and CTD are reversible structural alterations that appear in the first stages of the renal damage by vascular ablation. However, GC, TD, and CMH are lesions that have a significant effect in the glomerular-tubular relation, causing an irreversible damage in the renal function.

Subtotal nephrectomy induced a significant increase in TBARS (P = .0253) of 144%, whereas applications of ozone/oxygen gaseous mixture after subtotal nephrectomy increased TBARS to 90% (P = .0253) over the levels of positive control group (Table 3). SOD activity was significantly decreased to 55% (P = .0143) in positive control group, but, in ozone group, 39% of the enzymatic activity was recovered (P = .0253). Ozone therapy after subtotal nephrectomy induced a total increase in SOD activity of 94% (P = .0281). A similar behavior was observed for CAT enzymatic activity. In positive control group there was a significant decrease of 50%, whereas in ozone group a recovery of 218% was observed (P = .0143) in the enzymatic activity of CAT, indicating a total increase in CAT activity of 268% (P = .0034). GSH concentration and GSH-Px enzymatic activity were not significantly affected by subtotal nephrectomy in this animal model, but when fifteen intrarectal applications of ozone/oxygen gaseous mixture were applied we observed a significant stimulation of GSH-Px, as well as an increase in GSH concentration. Renal GSH concentration was significantly increased to 87% (P = .0253) whereas GSH-Px activity was increased to 39% (P = .0253) (Table 3).

### DISCUSSION

Animals submitted to the subtraction of 5/6 of the total renal mass moved forward the installation of the CRF, demonstrated by the decrease of RPF and GFR and the increase of SAP, plasma creatinine, protein excretion, decrease of potassium and sodium excretions, as well as the presence of renal damage in the histological study. This behavior is still more pronounced in the positive control group, where the renal damage reached 100%.

The results have shown, at the end of the study, that the animals treated with ozone had the highest figures of RPF and GFR, as well as lower figures of proteinuria, plasma creatinine concentration, higher urine excretion, and lower SAP in comparison with the positive control group. These results can be linked to the ozone antiplatelet activity [10], diminishing blood viscosity, that could produce a decrease in the friction between the blood and the glomerular vascular walls, decreasing the flow resistance, increasing the RPF and GFR, achieving similar figures to those shown in the Sham group. The flow rise contributes to diminishing the endothelial injuries and the glomerular collapse, avoiding the tubular hypoxia, the hemorrhages, and the release of several proinflammatory cytokines [40, 41, 42, 43].

A depression in SOD expression was reported previously [11] for the same CRF model that we used, that could be correlated with the observed diminution in the activity of SOD and CAT, which can contribute to
oxidative stress by increasing superoxide anion and hydrogen peroxide generation.

As it was reported before [14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24], ozone therapy is an oxidative approach that by provoking brief moments of oxidative stress, may stimulate antioxidant system to fight against the phenomenon per se. Thus, the significant increase in lipid peroxidation, measured in the form of TBARS, was expected after the surgical procedure, followed by fifteen ozone applications. In spite of the significant increase in TBARS, an increase in antioxidant status was seen in the ozone group. The increase in renal TBARS might not be related with an increase in renal damage because the remarkable increase in antioxidant system surpasses this effect, inducing a general status of antioxidant protection.

Renal damage in this model of CRF might correspond with generation of ROS, such as superoxide anion and hydrogen peroxide. Renal GSH concentration and GSH-Px activity might not be directly affected by subtotal nephrectomy in this model. However, ozone therapy induced a significant increase in renal GSH amount and GSH-Px activity ($P = .0253$), besides a remarkable stimulation of SOD and CAT activities, that surpass the increase in lipid peroxidation. This suggests that ozone therapy has a protective effect on renal tissue, by upregulation of the antioxidant system, protecting against the oxidative stress provoked by ischemia.

On the other hand, it had been demonstrated that ozone is able to regulate the calcium levels, maintaining its homeostasis, avoiding any damage to the cell structure [44]. Also, it is possible that the ozone therapy effect, with the stimulation of the antioxidant defense system [14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25], protected the tissues against the oxidative stress shown in CRF [6], being in correspondence with the positive histological results obtained, where the ozone group showed the lowest percent of glomerular collapse, tubule degeneration, and cortical-medullary hemorrhages compared with positive control group.

In conclusion, in this animal model of CRF, rectal administrations of ozone produced a delay in the advance of the disease, protecting the kidneys against the deleterious effects shown in the CRF. Consequently, whenever possible, ozone therapy may become an important therapy to improve the quality of life of patients suffering CRF.
